Monte_Carlo

April 2, 2018

1 Mini Project: Monte Carlo Methods

In this notebook, you will write your own implementations of many Monte Carlo (MC) algorithms.

While we have provided some starter code, you are welcome to erase these hints and write your code from scratch.

1.0.1 Part 0: Explore BlackjackEnv

Use the code cell below to create an instance of the Blackjack environment.

Each state is a 3-tuple of: - the player's current sum $\in \{0, 1, ..., 31\}$, - the dealer's face up card $\in \{1, ..., 10\}$, and - whether or not the player has a usable ace (no = 0, yes = 1).

The agent has two potential actions:

```
STICK = 0
HIT = 1
```

Verify this by running the code cell below.

Execute the code cell below to play Blackjack with a random policy.

(The code currently plays Blackjack three times - feel free to change this number, or to run the cell multiple times. The cell is designed for you to get some experience with the output that is returned as the agent interacts with the environment.)

```
action = env.action_space.sample()
                state, reward, done, info = env.step(action)
                if done:
                    print('End game! Reward: ', reward)
                    print('You won :)\n') if reward > 0 else print('You lost :(\n')
                    break
(13, 2, False)
End game! Reward: -1.0
You lost :(
(19, 10, False)
End game! Reward: -1
You lost :(
(21, 5, True)
(21, 5, False)
End game! Reward: 1.0
You won :)
```

1.0.2 Part 1: MC Prediction: State Values

In this section, you will write your own implementation of MC prediction (for estimating the state-value function).

We will begin by investigating a policy where the player always sticks if the sum of her cards exceeds 18. The function generate_episode_from_limit samples an episode using this policy.

The function accepts as **input**: - bj_env: This is an instance of OpenAI Gym's Blackjack environment.

It returns as **output**: - episode: This is a list of (state, action, reward) tuples (of tuples) and corresponds to $(S_0, A_0, R_1, \ldots, S_{T-1}, A_{T-1}, R_T)$, where T is the final time step. In particular, episode[i] returns (S_i, A_i, R_{i+1}) , and episode[i][0], episode[i][1], and episode[i][2] return S_i , A_i , and R_{i+1} , respectively.

Execute the code cell below to play Blackjack with the policy.

(The code currently plays Blackjack three times - feel free to change this number, or to run the cell multiple times. The cell is designed for you to gain some familiarity with the output of the generate_episode_from_limit function.)

Now, you are ready to write your own implementation of MC prediction. Feel free to implement either first-visit or every-visit MC prediction; in the case of the Blackjack environment, the techniques are equivalent.

Your algorithm has three arguments: - env: This is an instance of an OpenAI Gym environment. - num_episodes: This is the number of episodes that are generated through agent-environment interaction. - generate_episode: This is a function that returns an episode of interaction. - gamma: This is the discount rate. It must be a value between 0 and 1, inclusive (default value: 1).

The algorithm returns as output: - V: This is a dictionary where V[s] is the estimated value of state s. For example, if your code returns the following output:

```
{(4, 7, False): -0.38775510204081631, (18, 6, False): -0.58434296365330851, (13, 2, False): -0.4
```

then the value of state (4, 7, False) was estimated to be -0.38775510204081631.

If you are unfamiliar with how to use defaultdict in Python, you are encouraged to check out this source.

```
In [6]: from collections import defaultdict
        import numpy as np
        import sys
        def mc_prediction_v(env, num_episodes, generate_episode, gamma=1.0):
            # initialize empty dictionary of lists
            returns = defaultdict(list)
            # loop over episodes
            for i_episode in range(1, num_episodes+1):
                # monitor progress
                if i_episode % 1000 == 0:
                    print("\rEpisode {}/{}.".format(i_episode, num_episodes), end="")
                    sys.stdout.flush()
                ## TODO: complete the function
                # first-visit algorithm
                episode = generate_episode_from_limit(env);
                states, actions, rewards = zip(*episode);
                EachEpisode = defaultdict(int);
```

```
for i, state in enumerate(states):
    if EachEpisode[state] == 0:
        returns[state].append(np.sum(rewards[i:]));

V = { i: np.mean(v) for i, v in returns.items()}
return V
```

Use the cell below to calculate and plot the state-value function estimate. (*The code for plotting the value function has been borrowed from this source and slightly adapted.*)

To check the accuracy of your implementation, compare the plot below to the corresponding plot in the solutions notebook **Monte_Carlo_Solution.ipynb**.

1.0.3 Part 2: MC Prediction: Action Values

In this section, you will write your own implementation of MC prediction (for estimating the action-value function).

We will begin by investigating a policy where the player *almost* always sticks if the sum of her cards exceeds 18. In particular, she selects action STICK with 80% probability if the sum is greater than 18; and, if the sum is 18 or below, she selects action HIT with 80% probability. The function generate_episode_from_limit_stochastic samples an episode using this policy.

The function accepts as **input**: - bj_env: This is an instance of OpenAI Gym's Blackjack environment.

It returns as **output**: - episode: This is a list of (state, action, reward) tuples (of tuples) and corresponds to $(S_0, A_0, R_1, \ldots, S_{T-1}, A_{T-1}, R_T)$, where T is the final time step. In particular, episode[i] returns (S_i, A_i, R_{i+1}) , and episode[i][0], episode[i][1], and episode[i][2] return S_i , A_i , and R_{i+1} , respectively.

```
if done:
    break
return episode
```

Now, you are ready to write your own implementation of MC prediction. Feel free to implement either first-visit or every-visit MC prediction; in the case of the Blackjack environment, the techniques are equivalent.

Your algorithm has three arguments: - env: This is an instance of an OpenAI Gym environment. - num_episodes: This is the number of episodes that are generated through agent-environment interaction. - generate_episode: This is a function that returns an episode of interaction. - gamma: This is the discount rate. It must be a value between 0 and 1, inclusive (default value: 1).

The algorithm returns as output: - Q: This is a dictionary (of one-dimensional arrays) where Q[s][a] is the estimated action value corresponding to state s and action a.

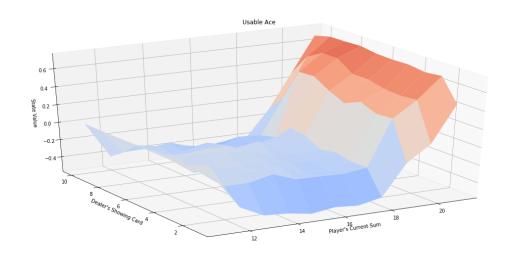

```
In [9]: def mc_prediction_q(env, num_episodes, generate_episode, gamma=1.0):
            # initialize empty dictionaries of arrays
            returns_sum = defaultdict(lambda: np.zeros(env.action_space.n))
            N = defaultdict(lambda: np.zeros(env.action_space.n))
            Q = defaultdict(lambda: np.zeros(env.action_space.n))
            # loop over episodes
            for i_episode in range(1, num_episodes+1):
                # monitor progress
                if i_episode % 1000 == 0:
                    print("\rEpisode {}/{}.".format(i_episode, num_episodes), end="")
                    sys.stdout.flush()
                ## TODO: complete the function
                # first-visit
                # generate episode
                episode = generate_episode_from_limit_stochastic(env);
                states, actions, rewards = zip(*episode);
                EachEpisode = defaultdict(lambda: np.zeros(env.action_space.n));
                for ii, state in enumerate(states):
                    action = actions[ii];
                    if EachEpisode[state][action] == 0:
                        N[state][action] += 1;
                        returns_sum[state] [action] += np.sum(rewards[ii:]);
                        Q[state] [action] = returns_sum[state] [action] /N[state] [action];
            return Q
```

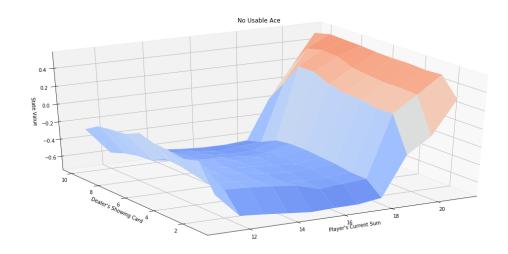

Use the cell below to obtain the action-value function estimate *Q*. We have also plotted the corresponding state-value function.

To check the accuracy of your implementation, compare the plot below to the corresponding plot in the solutions notebook **Monte_Carlo_Solution.ipynb**.

Episode 500000/500000.

plot_blackjack_values(V_to_plot)

In [18]: Q = mc_prediction_q(env, 500000, generate_episode_from_limit_stochastic)
Episode 500000/500000.

```
Out[18]: array([ 0., 0.])
In [20]: for k, v in Q.items():
                 print(k, v)

1.0.4 Part 3: MC Control: GLIE

In this section, you will write your own implementation of constant- α MC control.

Your algorithm has three arguments: - env: This is an instance of an OpenAI Gym environment. - num_episodes: This is the number of episodes that are generated through agent-environment interaction. - gamma: This is the discount rate. It must be a value between 0 and 1, inclusive (default value: 1).

The algorithm returns as output: - Q: This is a dictionary (of one-dimensional arrays) where Q[s][a] is the estimated action value corresponding to state s and action a. - policy: This is a dictionary where policy[s] returns the action that the agent chooses after observing state s.

(Feel free to define additional functions to help you to organize your code.)

```
In [26]: episilon = 0.05;
         epi_greedy(Q, episilon)
Out[26]: defaultdict(int,
                      {(10, 1, False): 1,
                       (10, 10, False): 1,
                       (10, 2, False): 1,
                       (10, 3, False): 1,
                       (10, 4, False): 1,

        Q[state][action] += (np.sum(rewards[ii:]) - Q[state][action])/N[state][
policy = dict((k, np.argmax(v)) for k, v in Q.items())
return policy, Q
```

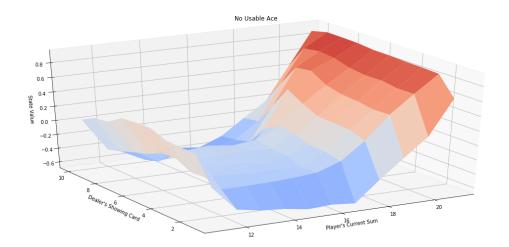

Use the cell below to obtain the estimated optimal policy and action-value function.

```
In [71]: # obtain the estimated optimal policy and action-value function
    policy_glie, Q_glie = mc_control_GLIE(env, 500000)
```

Next, we plot the corresponding state-value function.

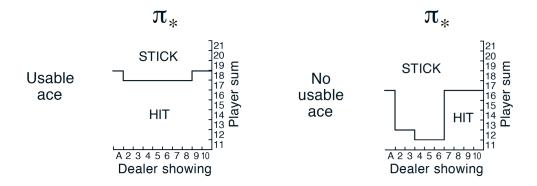

Episode 500000/500000.

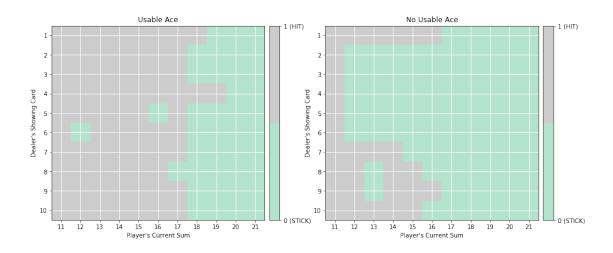

Finally, we visualize the policy that is estimated to be optimal.

```
In [73]: from plot_utils import plot_policy
    # plot the policy
    plot_policy(policy_glie)
```

True Optimal Policy

The **true** optimal policy π_* can be found on page 82 of the textbook (and appears below). Compare your final estimate to the optimal policy - how close are you able to get? If you are not happy with the performance of your algorithm, take the time to tweak the decay rate of ϵ and/or run the algorithm for more episodes to attain better results.

1.0.5 Part 4: MC Control: Constant- α

In this section, you will write your own implementation of constant- α MC control.

Your algorithm has four arguments: - env: This is an instance of an OpenAI Gym environment. - num_episodes: This is the number of episodes that are generated through agent-environment interaction. - alpha: This is the step-size parameter for the update step. - gamma: This is the discount rate. It must be a value between 0 and 1, inclusive (default value: 1).

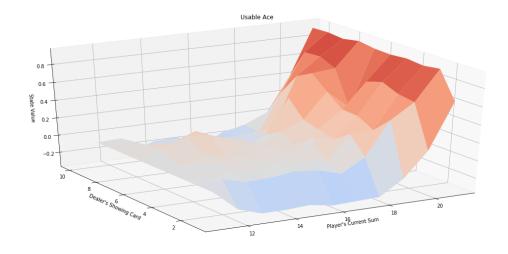

The algorithm returns as output: - Q: This is a dictionary (of one-dimensional arrays) where Q[s][a] is the estimated action value corresponding to state s and action a. - policy: This is a dictionary where policy[s] returns the action that the agent chooses after observing state s.

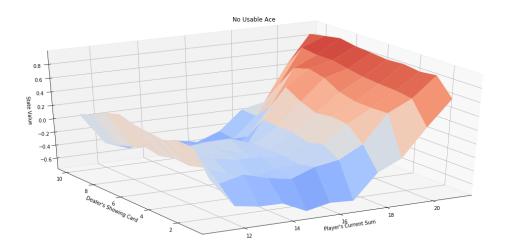

(Feel free to define additional functions to help you to organize your code.)

```
# initialize empty dictionary of arrays
Q = defaultdict(lambda: np.zeros(nA))
# loop over episodes
for i_episode in range(1, num_episodes+1):
    # monitor progress
    if i_episode % 1000 == 0:
        print("\rEpisode {}/{}.".format(i_episode, num_episodes), end="")
        sys.stdout.flush()
    ## TODO: complete the function
    epsilon = 1.0/((i_episode/8000)+1);
    episode = generate_episode_from_limit_policy(env, Q, epsilon, nA);
    states, actions, rewards = zip(*episode);
    EachEpisode = defaultdict(lambda: np.zeros(env.action_space.n));
    for ii, state in enumerate(states):
        action = actions[ii];
        if EachEpisode[state][action] == 0:
            Q[state] [action] += alpha*(np.sum(rewards[ii:]) - Q[state] [action]);
policy = dict((k, np.argmax(v)) for k, v in Q.items())
return policy, Q
```

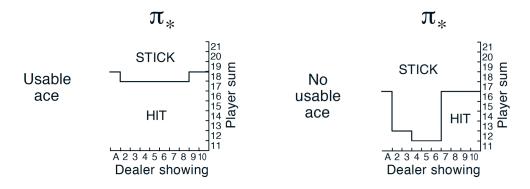

Use the cell below to obtain the estimated optimal policy and action-value function.

Next, we plot the corresponding state-value function.

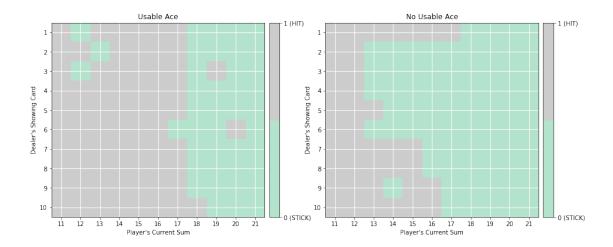

Finally, we visualize the policy that is estimated to be optimal.

True Optimal Policy

The **true** optimal policy π_* can be found on page 82 of the textbook (and appears below). Compare your final estimate to the optimal policy - how close are you able to get? If you are not happy with the performance of your algorithm, take the time to tweak the decay rate of ϵ , change the value of α , and/or run the algorithm for more episodes to attain better results.
